Abstract

Parkinson's disease is the second most common neurodegenerative disorder; it affects 1% of the population over the age of 65. The number of people with Parkinson's disease is set to rapidly increase due to changing demographics and there is an unmet clinical need for disease-modifying therapies. The pathological hallmarks of Parkinson's disease are the progressive degeneration of dopaminergic neurons in the substantia nigra and their axons which project to the striatum, and the aggregation of α -synuclein; these result in a range of debilitating motor and non-motor symptoms. The application of neurotrophic factors to protect and potentially regenerate the remaining dopaminergic neurons is a major area of research interest. However, this strategy has had limited success to date. Clinical trials of two well-known neurotrophic factors, glial cell line-derived neurotrophic factor and neurturin, have reported limited efficacy in Parkinson's disease patients, despite these factors showing potent neurotrophic actions in animal studies. There is therefore a need to identify other neurotrophic factors that can protect against α -synuclein-induced degeneration of dopaminergic neurons. The bone morphogenetic protein (BMP) family is the largest subgroup of the transforming growth factor- β superfamily of proteins. BMPs are naturally secreted proteins that play crucial roles throughout the developing nervous system. Importantly, many BMPs have been shown to be potent neurotrophic factors for dopaminergic neurons. Here we discuss recent work showing that transcripts for the BMP receptors and BMP2 are co-expressed with several key markers of dopaminergic neurons in the human substantia nigra, and evidence for downregulation of BMP2 expression at distinct stages of Parkinson's disease. We also discuss studies that explored the effects of BMP2 treatment, in *in vitro* and *in vivo* models of Parkinson's disease. These studies found potent effects of BMP2 on dopaminergic neurites, which is important given that axon degeneration is increasingly recognized as a key early event in Parkinson's disease. Thus, the aim of this mini-review is to give an overview of the BMP family and the BMP-Smad signalling pathway, in addition to reviewing the available evidence demonstrating the potential of BMP2 for Parkinson's disease therapy.

Key Words: axon growth; BMP2; dopaminergic neurons; neuroprotection; neurotrophic factor; neuroregeneration; Parkinson's disease; α -synuclein

Introduction

Parkinson's disease (PD) is a common neurodegenerative disorder, the pathological hallmarks of which are the progressive degeneration of nigrostriatal midbrain dopaminergic (mDA) neurons and intraneuronal inclusions of α -synuclein, known as Lewy bodies and Lewy neurites (Spillantini et al., 1997; O'Keeffe and Sullivan, 2018). There is increasing evidence that axonal degeneration, potentially mediated by α -synuclein, may be a key early event in the pathogenesis of PD (O'Keeffe and Sullivan, 2018). Since there is a lack of disease-modifying therapies for PD, two experimental therapies focusing on neuroprotection and neurorepair have been trialed. These are: (i) administration of neurotrophic factors to protect the remaining mDA neurons from degeneration, and (ii) grafting of fetal midbrain neurons to replace the mDA neurons that have been lost (Hegarty et al., 2014a). For the purpose of this review, we will focus on the former.

Search Strategy and Selection Criteria

For this review we searched NCBI and Science Direct for

literature published from inception to September 28, 2019 for articles referencing one or more of the following: BMP2; BMP; Neurotrophic Factor; Dopaminergic neurons; Parkinson's disease.

The Bone Morphogenetic Protein Family

Neurotrophic factors (NTFs) are small secreted proteins that regulate the development, survival, growth, differentiation and maturation of discrete neuronal populations (Sullivan and O'Keeffe, 2016). In PD, two of the most widely studied dopaminergic NTFs are glial cell line-derived neurotrophic factor (GDNF) and neurturin, both of which are members of the transforming growth factor- β (TGF- β) superfamily of cytokines. GDNF and neurturin showed potent neurotrophic effects in *in vitro* and *in vivo* models of PD, which led to their subsequent clinical testing in PD patients (Nutt et al., 2003; Patel et al., 2005; Slevin et al., 2005; Lang et al., 2006; Decressac et al., 2011; Warren Olanow et al., 2015; Whone et al., 2019a, b). However, these clinical trials have thus far failed to meet their primary endpoints. Consequently, there

is an ongoing need to identify alternative NTFs for dopaminergic neuroprotection in PD. Bone morphogenetic proteins (BMPs) are being increasingly studied in this regard.

The BMP family is the largest subgroup of the TGF- β superfamily of proteins and is comprised of at least 20 growth factors, including the growth and differentiation factor (GDF) family (Kawabata et al., 1998). BMPs were first identified by their presence in extracts of demineralized bone (Wozney, 1992) and have since been shown to induce a sequential developmental cascade of cartilage and bone formation, as well as playing roles in various other developmental processes (Chen et al., 2004). Experimental evidence has demonstrated that BMPs are involved in many biological processes across various cell types, including monocytes, epithelial cells, mesenchymal cells, and importantly, neuronal cells (Miyazono and Shimanuki, 2008; Wang et al., 2014). Within these cells, BMPs are known to regulate growth, differentiation, chemotaxis and apoptosis, while also playing vital roles in the morphogenesis of almost all organs and tissues throughout embryogenesis (Hogan, 1996; Wang et al., 2014). Additionally, BMPs are crucial regulators of axonal growth in many distinct neuronal populations (Gratacos et al., 2002; Parikh et al., 2011; Hegarty et al., 2013a).

Bone Morphogenetic Protein-Smad Signaling

BMPs signal through a canonical pathway that involves transcription factors known as Smads. In this pathway, BMPs bind to a heterotetrameric complex of cell surface transmembrane type I and type II serine/threonine kinase receptors, causing the subsequent activation of Smad signaling (Weiss and Attisano, 2013) (Figure 1). Depending on the cellular context, BMP signaling can also occur via non-canonical pathways involving the activation of many intracellular pathways, including GTPases, mitogen activated protein kinase, and phosphoinositide 3-kinase pathways (Zhang, 2009). To date, there are seven identified type I receptors, the activin receptor-like kinases (ALK) 1–7, and five type II receptors (Hegarty et al., 2013a). There are eight distinct Smad proteins, which constitute three separate functional groupings. These include the receptor-regulated Smads (R-Smads)-1, -2, -3, -5, and -8/9, the common-mediator Smad (Co-Smad) 4 and the inhibitory Smads (I-Smads) 6 and 7 (Wrana and Attisano, 2000). Following ligand binding to the heterotetrameric receptor complex, which is composed of a type I and type II receptor dimer, the constitutively active type II receptors intracellularly transphosphorylate the type I receptors at serine and threonine residues via a highly conserved glycine/serine domain (Wrana and Attisano, 2000). The phosphorylation of type I receptors leads to the recruitment and subsequent phosphorylation of the R-Smads, which can then form a heterotrimer complex with Co-Smad 4. The I-Smads function as major negative regulators of BMP-Smad signaling and compete with the R-Smads for both receptor binding and Co-Smad 4 binding. The I-Smads also target the receptors for degradation via the proteasome (Shi and Massague, 2003). The signaling pathway culminates with the R-Smads and Co-Smad 4 complex translocating to the nucleus, where it binds to DNA and regulates the transcription of target genes (Wrana and Attisano, 2000). However, although there are many ligands of the TGF- β superfamily, there are

Figure 1 Schematic of BMP-Smad signalling from cell membrane to nucleus.

BMP ligands bind to a heterotetrameric complex of type I and type II serine/threonine kinase cell surface receptors, causing the constitutively active type II receptor to intracellularly phosphorylate the type I receptor. R-Smads and I-Smads compete for binding at the receptor complex for phosphorylation and subsequent complex formation with Co-Smad 4. This complex translocates to the nucleus, where it binds to the DNA and alters transcription. BMP: Bone morphogenetic protein. BMPR: BMP receptor; Co-Smad 4: common-mediator Smad 4; I-Smads: inhibitory Smads; R-Smads: receptor-regulated Smads.

very few receptors available to accommodate ligand binding. Thus, the type I and type II receptors are required to bind to more than one ligand type (Shi and Massague, 2003). There are two known type I BMP receptors (BMPRs), BMPR1A (also known as ALK3) and BMPR1B (also known as ALK6); however, BMPs are also capable of binding to ALK1 and 2. Furthermore, BMPs can bind to three type II receptors: BMPR2, activin type 2A receptor and activin type 2B receptor (Hegarty et al., 2013a). Recent studies have identified dynamin-dependent endocytosis to be a crucial regulator of the BMPRs at the surface of the cell membrane and to play a central role in the activation, temporal kinetics and magnitude of BMP signal transduction (Hegarty et al., 2017a).

The type I and II BMPRs can form the heterotetrameric complex required for Smad activation in various ways; consequently, BMP ligands have varying affinities for these combinations. For example, BMP2 binds to BMPR1A and BMPR1B with a higher affinity than it does to BMPR2. Similarly, GDF5 binds to BMPR2 and BMPR1B with greater affinity than to BMPR1A. In fact, the affinity of GDF5 for BMPR1B is at least 15-fold higher than it is for BMPR1A, signifying the fundamental importance of BMPR1B for GDF5 signaling (Nickel et al., 2005). Such varying affinities for multiple receptor complexes is relevant when studying the effects of potential NTFs in different cell lines. In addition, various studies on the structural and functional features of the BMPRs have highlighted a cytoplasmic loop segment, known as the L45 loop, located adjacent to the glycine/serine domain on type I receptors, which is involved in R-Smad binding. A corresponding loop, the L3 loop, is present on the R-Smads and is

involved in determining the specific Smad substrates for the type I receptor kinases. Smads 1, 5 and 8 are the pivotal effectors that are primarily linked to members of the BMP/GDF subfamily, while Smad 2 and 3 are typically associated with TGF- β s, Activins and Nodals (Mueller and Nickel, 2012).

Bone Morphogenetic Protein Expression in the Nervous System

Several studies have characterized the temporal expression profiles of the various BMPs and their receptors in the developing nervous system. *BMPR1* and *BMPR2* are stably expressed in the brain throughout adulthood, in several regions including the cortex, striatum, hippocampus and substantia nigra (SN) (Chen et al., 2003; Miyagi et al., 2011). The expression of *BMPR1B* and *BMPR2* receptors in the rat ventral mesencephalon (VM) is present from embryonic day (E) 14 onwards, after which it is continuous through to at least post-natal day (P) 90 (for review see Hegarty et al., 2014b). Similarly, *BMPR1B* and *BMPR2* transcripts are expressed in the mouse VM from E12 onwards (Hegarty et al., 2017b). Notably, this BMPR temporal expression profile parallels the growth of nigrostriatal dopaminergic projections. While multiple BMPs have been examined as potential NTFs for mDA neurons (for review see Hegarty et al., 2014b), given recent data showing that *BMP2* is expressed in the human SN, and that it can protect against neurotoxin and α -synuclein-induced degeneration (Goulding et al., 2019), we will focus on *BMP2* for the purposes of this article.

Neurotrophic Effects of Bone Morphogenetic Protein 2 in Primary Cultures of Rodent Midbrain

Within the BMP family, *BMP2* is one of the most extensively studied BMPs. An early paper reported that recombinant human (rh)*BMP2* exerted neurotrophic effects on cultured E13–15 rat VM mDA neurons (Jordan et al., 1997). Specifically, treatment with 10 ng/mL rh*BMP2* increased the survival of tyrosine hydroxylase-positive (TH⁺) mDA neurons, by 1.5-fold compared to that in controls, after 8 days *in vitro* (DIV). The same study demonstrated that *BMP2* treatment of mDA cultures resulted in increased numbers of 5-bromodeoxyuridine-positive and glial fibrillary acidic protein-positive cells, markers of cell proliferation and astrocytes, respectively. These early findings indicated not only does *BMP2* promote the survival of mDA neurons, but that it also appears to play a selective role in the proliferation and differentiation of neural progenitors.

A further study also demonstrated positive effects of *BMP2* treatment on mDA neurons in E14 VM cultures. Specifically, cultures treated with *BMP2* displayed a concentration-dependent increase in the number of mDA neurons, reaching a maximum increase of 237% after treatment with 10 ng/mL, compared to vehicle-treated controls after 7 DIV (Reiriz et al., 1999). In addition, *BMP2* treatment increased the number of primary neurites and neurite branching in TH⁺ cells in a concentration-dependent manner, reaching a maximal effect with 1 ng/mL rh*BMP2* (Reiriz et al., 1999). Similarly, other studies have shown a significant increase in the neurite

length of TH⁺ neurons in E14 rat VM primary cultures after treatment with 50 ng/mL or 200 ng/mL rh*BMP2* (Hegarty et al., 2014b; Goulding et al., 2019). One study investigated whether *BMP2*-induced effects were mediated by astroglial cells and reported that addition of 10 ng/mL *BMP2* had no effect on the number or morphology of astroglial cells in E14 VM cultures (Reiriz et al., 1999). They further showed that *BMP2*-induced increases in TH⁺ cell numbers were not altered in the presence of 30 μ M α -aminoadipic acid, a gliotoxin that eliminates glial fibrillary acidic protein-immunoreactive astrocytes (Reiriz et al., 1999). Interestingly however, this study did report that treatment with 100 ng/mL *BMP2* led to significant increases in both the number and morphology of astrocytes (Reiriz et al., 1999). These findings suggest that, at low doses, *BMP2* treatment promotes both the number and morphological differentiation of mDA neurons, while at higher doses, it also influences the number and phenotype of astroglial cells (Reiriz et al., 1999).

Several studies have reported that the neurotrophic effects of *BMP2* and BMP signalling often occur in tandem with, and are amplified by, other NTFs. For example, *BMP2*-induced signalling in E19 rat striatal neurons was found to be facilitated by co-administration with either BDNF or neurotrophin-3 (Gratacos et al., 2001). However, there is limited data available on the interactions of BMPs with other NTFs in the context of dopaminergic neurons, and this will be an important point to consider in future research.

Neurotrophic Effects of Bone Morphogenetic Protein 2 in Cell Line Models of Human Dopaminergic Neurons

In addition to the neurotrophic effects of *BMP2* reported in studies on primary VM cultures, similar effects have been demonstrated in SH-SY5Y cells, a cell line which, despite some limitations, is a widely-used *in vitro* model of human mDA neurons (Xie et al., 2010; Hegarty et al., 2016; Xicoy et al., 2017; Goulding et al., 2019). Specifically, SH-SY5Y cells treated with 50 ng/mL or 200 ng/mL rh*BMP2* for 3 or 4 DIV respectively, displayed an increase in total neurite length (Hegarty et al., 2013b; Goulding et al., 2019). This supported the previous studies which showed that *BMP2* treatment induced neuronal differentiation of mDA neurons (Reiriz et al., 1999; Hegarty et al., 2014b; Goulding et al., 2019). Treatment with *BMP2* was also found to activate the canonical Smad 1/5/8 signaling pathway in SH-SY5Y cells to induce neurite growth (Hegarty et al., 2013b). A causal link between neurite growth and BMP signaling was demonstrated when it was shown that pretreatment with dorsomorphin, a selective small molecule inhibitor of *BMPR1* receptors (Yu et al., 2008; Hegarty et al., 2013b), completely prevented *BMP2*-induced differentiation of SHSY5Y cells (Hegarty et al., 2013b). In addition, dorsomorphin treatment completely blocked *BMP2*-induced Smad activation. Similar experiments on E14 VM cultures showed that dorsomorphin blocked both morphological differentiation of mDA neurons and activation of the Smad pathway, which had been induced by *BMP2* treatment (Hegarty et al., 2013b, 2014b). Collectively, these studies show that the phenotypic effects exerted by *BMP2* are directly dependent on the activation of the Smad 1/5/8 signaling pathway in mDA neurons (Hegarty et al., 2013b, 2014b).

Expression of Bone Morphogenetic Protein 2 and Its Receptors in the Human Substantia Nigra

We have recently shown, using unbiased co-expression analysis, that the expression of BMP2 and of its receptors is positively correlated with the expression of five key dopaminergic markers in the human SN, that is ALDH1A1, Nurr1, Girk2, TH and LMX1B (Goulding et al., 2019). Furthermore, we have shown that BMP2 is expressed at significantly higher levels in the SN than in the putamen or the cerebellum, areas that are known to be especially responsive to BMPs. Interestingly, we have also analyzed open source gene expression data from SN of age- and gender-matched samples at various Braak stages of PD and found that transcripts for BMP2 were significantly downregulated at later stages (Goulding et al., 2019). These data suggest a functional role for both BMP2 and the BMPRs in dopaminergic neurons within the human SN.

Protective Effects of Bone Morphogenetic Protein 2 against Neurotoxin- and α -Synuclein-Induced Neurodegeneration *In Vitro*

On investigating the effects of rhBMP2 in cellular *in vitro* models of PD, we found that treatment with 50 ng/mL rhBMP2 for 72 hours increased neurite length by 1.5-fold in SH-SY5Y cells and 1.3-fold in E14 VM cultures, compared to controls (Figure 2). Additionally, BMP2 treatment protected the survival of TH⁺ neurons in these mDA neuronal cultures against reductions induced by either 1-methyl-4-phenylpyridinium iodide or 6-hydroxydopamine (6-OHDA). Furthermore, treatment with 50 ng/mL rhBMP2 resulted in significant increases in both neurite length and somal area, in cultures treated with either 1-methyl-4-phenylpyridinium iodide or 6-OHDA for 72 hours (Goulding et al., 2019). Additionally, treatment with 50 ng/mL rhBMP2 protected against wild-type- α -synuclein- and mutant A53T- α -synuclein-induced neurite degeneration in both SH-SY5Y cells and in mDA neurons after 3 DIV (Goulding et al., 2019). This is important given that neurite degeneration is an early pathological feature of PD pathogenesis, which may be as a result of α -synuclein accumulation (O'Keeffe and Sullivan, 2018).

Neurotrophic effects of Bone Morphogenetic Protein 2 *In Vivo*

To support the positive neuroprotective effects of BMP2 seen in the *in vitro* studies, there are some promising data regarding its *in vivo* effects. One study reported that pretreatment with 50 ng/mL rhBMP2 could maintain cell viability in cultures of E14 VM for up to 6 hours, compared to untreated control cultures which demonstrated a 25% decrease in cell viability over the same period (Espejo et al., 1999). A subsequent *in vivo* study showed that treatment of E14 rat VM with 50 ng/mL rhBMP2 prior to grafting into the striatum of 6-OHDA-lesioned rats resulted in a significant increase in the survival of the grafted dopaminergic neurons (Espejo et al., 1999). This neuroprotective effect of BMP2 pretreat-

ment *in vivo* was substantial at 1 week after grafting, and remained, although at a lower level, after 4 weeks (Espejo et al., 1999). After 1 week, the rats that had received BMP2-treated VM grafts showed no difference in motor impairment, as measured by apomorphine-induced rotations, than those that had received untreated VM grafts; however after four weeks, rats with BMP2-treated VM grafts displayed significant reductions in rotations, compared to those with untreated grafts. Furthermore, the morphology of the grafted dopaminergic neurons was notably more differentiated in the rhBMP2 pre-treated group than in the untreated graft group at 4 weeks post-grafting (Espejo et al., 1999). In light of these studies showing the *in vivo* potential of BMP2 treatment, it will be important to test both recombinant BMP2 and viral vectors carrying the BMP2 transgene in neurotoxin and α -synuclein *in vivo* models of PD.

As well as the neurotrophic effects of BMP2 described above, another study has highlighted the potential of BMP2 to induce differentiation of neural stem cells (NSCs) *in vitro* (Yan et al., 2016). This is an important finding, given the low survival rate, and considering the ethical and logistical difficulties involved, of human fetal VM tissue grafts for PD treatment (Olanow et al., 2003; Ishii and Eto, 2014). Specifically, Yan et al. (2016) employed five doses of BMP2 (that is 0.1, 1, 10, 20 and 100 ng/mL) over a 14-day period, to treat NSCs harvested from E14 VM cells. This study found that 20 and 100 ng/mL doses of BMP2 induced the highest increases in the number of dopaminergic neurons, while also increasing their neurite length (Yan et al., 2016). This effect of BMP2 on NSC differentiation was induced via miR-145-mediated upregulation of Nurr1, a key player in the maintenance of DA neurons (Yan et al., 2016). NSCs offer a viable therapeutic approach to PD therapy as the cells are self-renewing and can be differentiated into all neural lineage cells, therefore showing promising potential to be used for replacement of those mDA neurons that are lost from the PD brain.

Conclusion

Here we have reviewed the available evidence that supports BMP2 as a factor with potential to be used in neurotrophic therapy for PD. It will be important to determine whether this BMP ligand is effective in protecting dopaminergic neurons against α -synuclein-induced degeneration *in vivo*, in translational models of PD, such as the α -synuclein rat model, as the next stage in rationalizing its further study as a potential therapeutic agent for PD.
